**All roads lead to market integration.
Lessons from a spatial analysis of the wheat market in 18th century Spain.¹**

Alexandra L. Cermeño (Lund University)²

Carlos Santiago-Caballero (Universidad Carlos III)³

ABSTRACT

This paper uses newly collected data from a large-scale census (*Catastro de la Ensenada*) to investigate the scale and causes of market integration in eighteenth century Spain. We use wheat prices observed in more than 5,200 municipalities to analyse the local spatial dependence of prices. We detect several regional clusters in the centre and coasts but find that these were not integrated with each other. We then investigate the first nature, second nature, and demand side determinants of these clusters and find that although geographical constraints like terrain roughness play a negatively significant role, the transportation network allowed connected municipalities to alleviate such obstacles. Our results suggest that unfavourable geographical conditions can be overcome by investments in transportation infrastructures.

Keywords: Early modern, market integration, grain markets, prices, geography.

1. Introduction

As states rose, so did markets. The complex relationship between state-building and the development of markets has been analysed in depth by authors like Epstein, who argued that as European countries consolidated and centralised their power, the subsequent reduction of transportation and transaction costs allowed the rise of domestic markets weakening the power of traditional monopolies (Epstein, 2000). Differences in the nature of this relationship in European economies explains in part, according to Epstein, the different paths of growth that they followed and processes like the Little Divergence. The extent to which political centralisation and nationalism translates into economic integration also reflects the ability of political elites to overcome the traditional barriers to the creation of a domestic market (Miladinovic, 2019). However, while the centralization of political power in eighteenth century Spain is well accepted, the existence of a highly integrated market is a more controversial debate in Spanish economic history. Were Spanish absolutist monarchs of the time able to use their political power to create a fully integrated domestic market?

Following Epstein's line of reasoning, the answer to the previous question would have long-lasting effects in the performance of the Spanish economy. There is a consensus in the traditional literature around the idea that the domestic market became integrated by mid-19th century thanks to the transport revolution and the effect of the railroads (Sánchez Albornoz, 1974, 1975, and Peña and Sánchez Albornoz, 1983, 1984). However, more recent studies suggest that the Spanish economy was already relatively well integrated in the mid-eighteenth century (Llopis Agelán and Sotoca López, 2005), and that integration levels during the eighteenth century were in fact higher than those achieved in later periods (Llopis and Agelán and Jeréz Méndez, 2001). Similarly, Reher (2001) argues that economic integration levels in preindustrial Spain were low, but that they increased during the eighteenth century as proved by the reduction in the volatility of prices over time. Gafe (2011) supported the existence of well integrated markets at regional levels, but rejected the existence of a national market in Spain in the eighteenth century. Regarding the sources behind increasing market integration, the most recent literature has highlighted the role of transports, especially the distance to the transport network reducing price differentials between markets (Schulze and Wolf, 2012; Federico and Sharp, 2013) as well as the importance of flows of information (Gao and Lei, 2019). This paper analyses the levels of economic integration in mid-eighteenth century Spain, following the revisionist hypothesis that this was a period of relatively high integration, and assesses the role played by the transportation network. For this purpose, we study wheat prices from the Crown of Castile, at the level of municipalities available from the *Catastro de la Ensenada*, a territory that represented around 80 percent of current Spain.

We analyse the prices of wheat for over 5,200 municipalities and test for their spatial autocorrelation using Local Moran's Indexes and Getis-Ord statistics which identify patterns on the similarity of data across space. Our results are congruent with the revisionist literature and we find well integrated clusters at the regional level which are not, however, well integrated at the national level. To further investigate the reasons of the regional integration and global dis-integration, we calculate the prices' coefficients of variation on a random sample of municipalities and those within the 50 km buffer from

them. We then test econometrically which geographic and market variables had an impact on this pattern using Ordinary Least Squares and Two Stage Least Squares regressions, and explore the need to adjust for spatial interactions using Spatial Auto Regressive models. We find that these patterns are heavily influenced by geographic variables, but also that the road network developed and used by travellers and tradesmen helped market integration and helped to soften the negative effects of geographical barriers.

The paper proceeds by presenting our data sources in Section 2. We explain our methodology in Section 3. Section 4 describes our results and examines drivers of the patterns. We finally conclude in Section 5.

2. Sources and data

This paper uses the information from the municipal manuscripts that were created for each municipality in the Cadastre de la Ensenada. The Cadastre was a monumental work carried out during the reign of Fernando VI, whose main purpose was the estimation of wealth for the introduction of a new tax, the *única contribución* (single tax), to finance the increasing expenditures of the monarchy. The tax had to be paid by each municipality in the Crown of Castile and the estimation of the exact amount to be paid was based on the location's wealth and a set of objective criteria.⁴ For that purpose, an army of some 1,000 judges and 90,000 local experts was mobilised to measure every plot of land, count every tree and measure the wealth of every single family liable to pay to the Crown. A significant share of the enormous amount of documentation produced during the process has survived, putting at the disposal of researchers a unique source for the study of eighteenth century Spain. In our case, we consulted the *Respuestas Generales* or General answers, a questionnaire that the authorities of each municipality had to fill in. We concentrated especially on the questions related to local prices and units of measurement. The most important information that we extracted from the books of the Cadastre was the price of wheat at municipal level. We used the price of wheat to measure spatial economic integration, mainly because of its availability in practically all the municipalities and also for its common use to measure pre industrial market integration in the literature (for example, see Persson, 1999). For the construction of our dataset, we individually consulted the books of 5,271 municipalities, all the locations with information on prices and local units of measurement in the Cadastre.⁵ Question 14 in the questionnaire inquired about a list of the prices of the main items produced in each municipality and is the one from where we extracted the prices of wheat. However, although the currency was common (*reales*), there was a high regional diversity of measures determining volume or weight. We used the information contained in Question 9 of the books where the local authorities had to describe the units of measurement that they used in their municipality and from that we standardised all the prices in *reales* per *fanega*. Other

⁴ Although the Basque Regions were part of the Crown, they were not included in the Cadastre as they had a special taxation system.

⁵ Manuscript books with the general answers can be found in the *Respuestas Generales del Catastro de Ensenada* and accessed in <http://pares.mcu.es/Catastro/> A list and graphic description with all the included municipalities can be found in the appendix.

necessary information from the same books and from alternative sources was used in a smaller sample of locations used in our econometric analysis, presented and explained in detail in the specification of the different models in the following section.

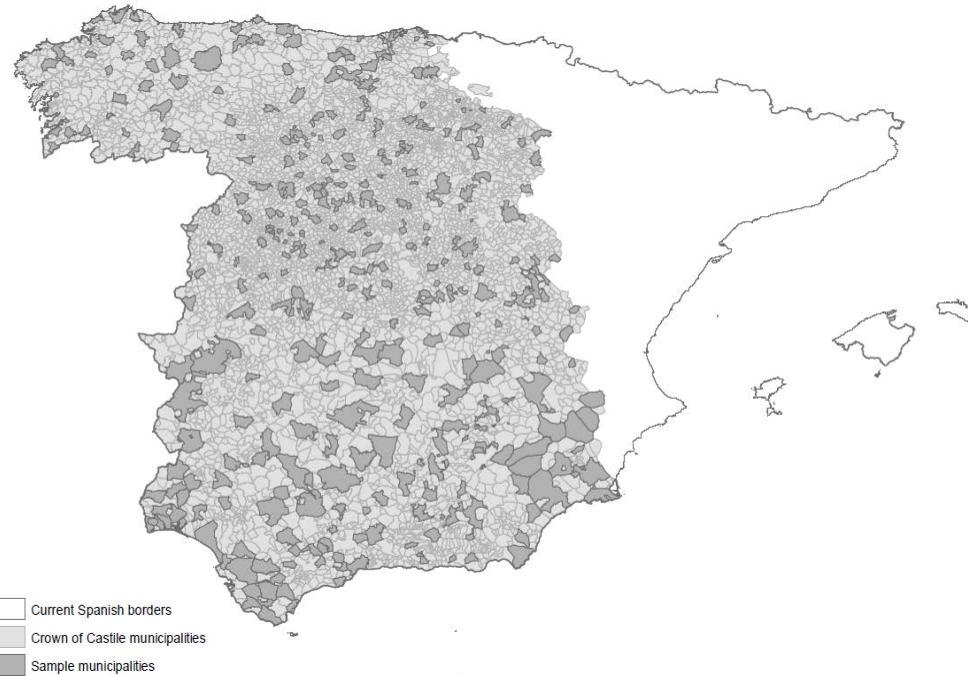

3. Methodology

We start our analysis by exploring the geographical distribution of wheat grain prices in the Crown of Castile, graphical representation is very useful to observe potential geographical patterns or clusters. The level of detail in this dataset (municipality) is adequate to observe how local prices affect or are affected by nearby markets and provide a chance to empirically demonstrate whether and how the Spanish market was integrated. Thus, we perform a spatial autocorrelation analysis using local indicators of spatial association (LISA) on our municipal wheat prices, more precisely the Local Moran's Index (I).⁶ This indicator of spatial association measures the incidence of spatial autocorrelation among adjacent and distant geographical locations based on a set of distance predefined criteria (i.e., neighboring matrixes). Global measures summarize the spatial autocorrelation in the sample, but local spatial indicators disentangle the correlation by geographical unit offering a value for each observation (municipalities in our case). The particularity of these local statistics is that they enable to graphically represent the spatial autocorrelations of prices and their significance levels. More than this, LISA indicators offer information about the values at which the correlations are significant, thus informing about the existence of high and low wheat price clusters.

After we explore the clusters in the market of wheat using the historical prices, we investigate the potential drivers of our results. In this section, we are forced to select a smaller sample of municipalities due to data restrictions, as there are no historical records available for all the municipalities in the Crown. We use a sample of 352 municipalities geographically scattered across the Crown of Castile territory that were randomly selected following Santiago-Caballero (2013a). The included municipalities range from coast to mountain, passing through the large internal plateaus, fertile valleys around the main rivers. The sample is not just geographically spread, but also contains diversity in socio-economic terms ranging from large urban centres to small rural villages and covers around 20 percent of the territory of the Crown of Castile. Figure 1 presents the population and sample municipalities.

⁶ We also used alternative estimators like the Getis-Ord statistic (Local G). The specification of the estimator and the results are presented in the appendices.

Figure 1. Population and sample of municipalities

Using this sample, we are able to gather a set of variables to assess the centripetal and centrifugal forces of market integration at municipal level. We present the descriptive statistics of these variables in Table 1. A good proxy of market integration is the variation of prices. Thus, we compute the coefficient of variation of the historical wheat prices of the selected municipalities and their neighbours whose centroid fall within their 50 km buffer zone, following Santiago-Caballero (2013a).⁷ Based on recent evidence, early modern pre industrial markets usually mattered to the hinterland up to 50 km (Cermeño and Enflo, 2019). Llopis and Sotoca (2007) confirm that trade in preindustrial Spain took place mostly within small distances. To allow for a more intuitive interpretation of our variable *Integration*, we estimated it as the logarithm of the inverse of the coefficient of variation for each municipality in the sample and their neighbours within a 50 km radius. Therefore, when there is less variation in the nearby prices, market integration is higher and our variable also takes higher values.

⁷ $\text{Integration} = 1/(CV) = 1((\text{Standard Deviation} / \text{Mean}) * 100)$.

Table 1: Descriptive statistics of sample variables

| | Mean | SD | Min | Max |
|--------------------------------|-------|-------|-------|-------|
| Dependent variable | | | | |
| Integration (log CV) | 1.012 | 0.177 | 0.399 | 1.454 |
| First nature variables | | | | |
| Altitude (m) | 628 | 272 | 61 | 1232 |
| Roughness (m) | 39.8 | 33.8 | 5.6 | 137.6 |
| Coast dummy | 0.12 | 0.33 | 0.00 | 1.00 |
| Distance to river in km | 10.5 | 14.5 | 0.001 | 87.7 |
| Second nature variables | | | | |
| Road dummy | 0.45 | 0.50 | 0 | 1 |
| Distance to road in km | 24.0 | 36.7 | 0.0 | 173.1 |
| Market variables | | | | |
| Yields | 7.58 | 2.88 | 1.89 | 19.21 |
| Price | 17.57 | 3.23 | 11.67 | 28.82 |
| Market potential (log) | 3.52 | 0.36 | 1.75 | 4.23 |
| Distance to Madrid in km | 261 | 126 | 29.8 | 516 |
| Number of municipalities | 352 | | | |

Notes: estimations using data from Catastro de la Ensenada

We then use *Integration* as a dependent variable in a regression to explore the determinants of the clusters of the market in the mid-18th century. Table 1 shows that the mean variation of prices in our 352 municipalities and their 50 km buffer zones is around ten percent ($10^{1.012}$), but there are large variations among observations. To study the determinants of these variations we use the following baseline equation:

$$Integration = \beta_0 + \beta_1 First\ nature + \beta_2 Second\ nature + \beta_3 Market \quad (1)$$

Geography has been considered one of the main obstacles to economic integration in preindustrial Spain (Grafe, 2011). Therefore, among the first nature factors that may impact market integration in this context, we consider several geographical variables that describe the municipalities' endowments. We include the log average *altitude* of all the municipalities within a distance of 50 kilometres around each observation, and measured *roughness* as their coefficient of variation. As shown in the descriptive statistics table, our sample's mean altitude is very close to the average altitude in Spain (600 metres over the sea level) and the ruggedness range of the sample terrain is ample (6 to 138 m). We expect both variables to be negatively correlated with market integration as they would, in principle, increase transport costs. We also include a dummy for those municipalities by the coast (12% of our sample) which can significantly enable trade and cabotage, and their log distance to rivers.

We also considered that market forces could have an impact in economic integration. For that reason, determinants related to the market both from the supply and demand side are also a part of our model. On the supply side, we estimate the average yields of wheat using the information from

Questions 9, 10 and 12 contained in books of the Cadastre for each location. Question 10 included a list of how the land was used and the areas that were dedicated to each cultivated item. Question 12 included information of the yields of the cultivated products depending on the quality of the land. As in the case of our estimation of prices, the existence of different regional units of measurement that also existed in the case of surface made necessary adjustments to obtain standardised yields. Once again, we use the information from Question 9, as surface units were usually put in terms of Castilian *varas* which allows us to estimate yields of wheat in quintals per hectare for the whole sample.

Demand or Boserupian forces are also taken into account to include the effect that demand-side incentives could have in the development of the market. High *prices* could act as incentive to integrate, as it would encourage producers to sell part of their output to the market. We estimate the average price for each 50 km buffer zone of our sample observations. Another important demand factor is the *market potential* faced by each location. As an alternative to population density, following Kopsidis and Wolf (2012) we estimate market potential as the sum of the potential urban demand weighted by the distance to each municipality in the sample.⁸ We expect both *price* and urban *market potential* to be positively correlated with market integration for the reasons described above. Further, we include distance to Madrid as an important market variable affecting agglomeration and market integration, since Madrid was the main market at the time, Ringrose (1983).

As the railroad did in the nineteenth century, investments to improve the transport network could have been used to overcome the geographical obstacles in the eighteenth century. Therefore, besides first nature geographic endowments, second nature variables such as manmade communication networks that can affect market integration were also included in our analysis. We expect that well connected municipalities would experience larger trade flows and, consequently, higher market integration. The role of roads requires a detailed analysis given their vital importance in Spain's domestic trade. Low rainfall levels in most of the country and its geography meant that internal transport relied on land transportation, and that the availability of navigable rivers and canals was very limited.

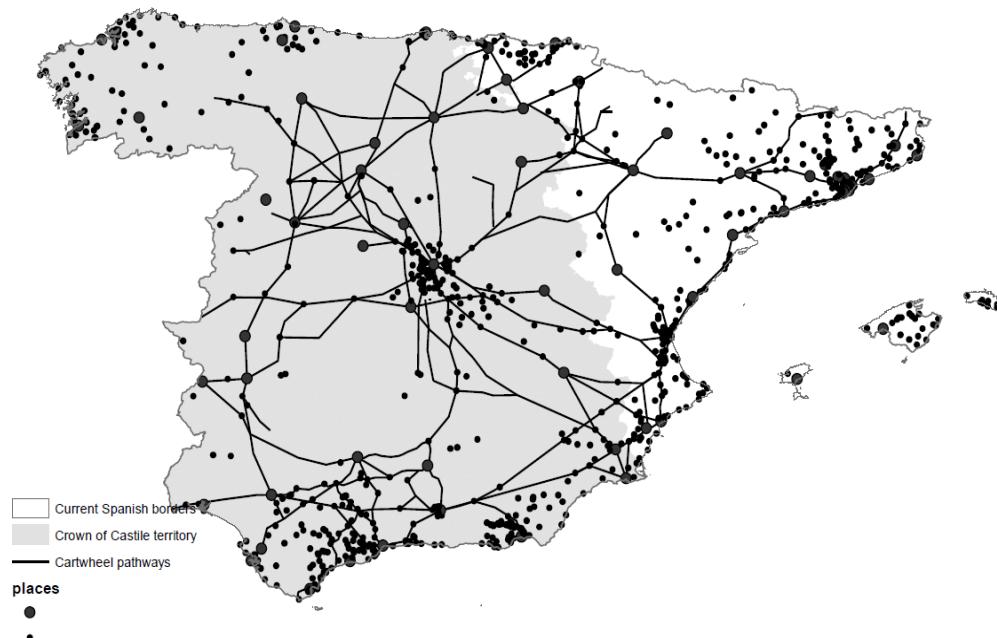

If in the sixteenth century the road network in Spain had reached 19,000 kilometres, by the early eighteenth century it had been reduced to not more than 11,000. In the same way the number of bridges and ferries also dwindled as a consequence of the lack of maintenance and poor investments. (Uriol, 2003:61). However, the network did not just lack size but also quality. Most of the roads in the early eighteenth century were not paved. Dust in the summer and mud in winter made them impracticable for long periods of time.⁹

⁸ We considered urban centers to be locations with more than 3,000 inhabitants.

⁹ This situation was well known by policymakers, as were their effects in the Spanish economy. The eighteenth century marked an inflection point, when investments resumed putting a special emphasis in the use of wagons instead of backpack animals. Leonardo Ward, an envoy of Carlos III sent to analyse the efficiency of the Spanish network wrote that: "Six animals can carry more weight in a wagon than twelve on their backs, and in a good road maybe only four of them are needed ... so we can see that the cost of transporting our goods through land

The improvements in the network included the transformation of old roads to new ones able to accommodate the use of wagons and also included construction works like the bridge of Toledo in the capital to connect Madrid with the south of Castile and the large urban centres of Andalusia. The connections with the north also improved with the works ordered by Fernando VI like the new path opened through the mountains of Guadarrama with the Alto del León, a paved pass that was finished in 1749 and connected the capital with the grain producing regions of Old Castile. The construction of better roads took place at the same time as the network was extended, and it is collected in “Itinerario Español”, Matías Escribano’s travel guide from 1758 that already included 12,500 kilometres. This publication describes the roads and the travel times from origin to destination of the paths that were commonly used by travellers. To measure the effect of these man-made roads which, in many cases were initially started as informal pathways, we have digitised this network using ArcGIS and calculated the shortest straight-line distance from our municipalities (Figure 2).

Figure 2. Places and cartwheel pathways in the mid-18th century

We use these variables and study their effect on market integration in several specifications using Ordinary Least Squares, Two Stage Least Squares, and test whether Spatial Autoregressive Models

can be reduced to one third, and therefore, the peasant that is 45 leagues away from the sea will have the same advantage than the one that is 15 leagues away, and it is easy to understand how this would help us to develop our agriculture, commerce and circulation Uriol (1978)

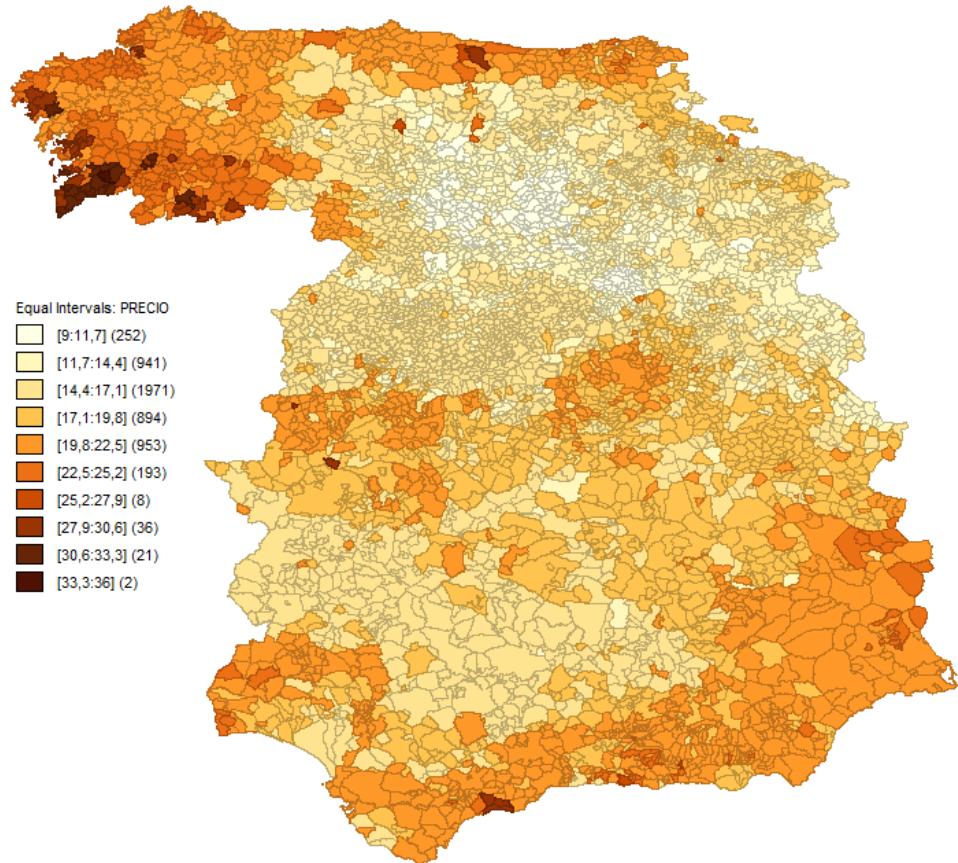

are more appropriate for this analysis given the found clustering patterns in the market. Next section presents these results.

4. Results

4.1. Descriptive maps

Figure 3 presents the geographical distribution of wheat prices in *reales per fanega* in the municipalities of the Crown of Castile included in our sample. The highest prices are located in the north-west of the country in the region of Galicia and in the coasts. We also observe clusters of high prices around large cities like Madrid and the north of Extremadura close to Portugal.

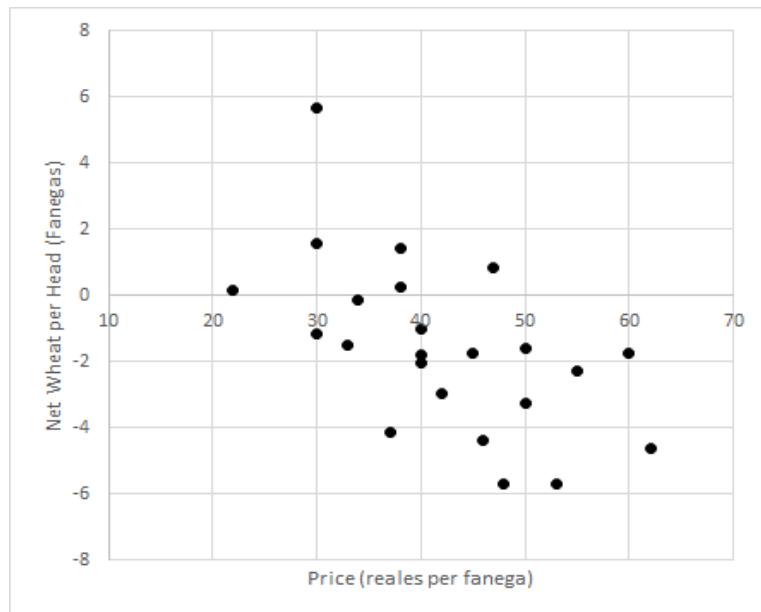

Figure 3: Price of wheat in the mid-18th century by decile (reales per fanega)

Source: Estimations from the Cadastre de la Ensenada.

The lowest prices can be systematically found in the provinces of Old Castile, especially those areas traditionally considered the granary of Spain characterised by large plains where the cultivation of grain was dominant and that were also able to reap higher yields than most of the country (Santiago-Caballero, 2013b). The highest prices correspond to areas surrounding large urban centres like Madrid and also the areas located near the coast that were also densely populated. To check the role played by supply and demand forces we used the information from the Censo de Frutos y Manufacturas of 1799, a survey where information regarding grain production, population and prices is provided at regional level. Figure 4 confirms that the differences between supply and demand help to explain the different signs of the integration clusters. The grain producing regions of Old Castile that enjoy a clear net surplus of wheat present lower prices than those regions more densely populated where the production of wheat was smaller.¹⁰

Figure 4: Wheat Prices vs Net Wheat Production per Head

Source: Calculations from the Censo de Frutos y Manufacturas (Polo y Catalina, 1803)

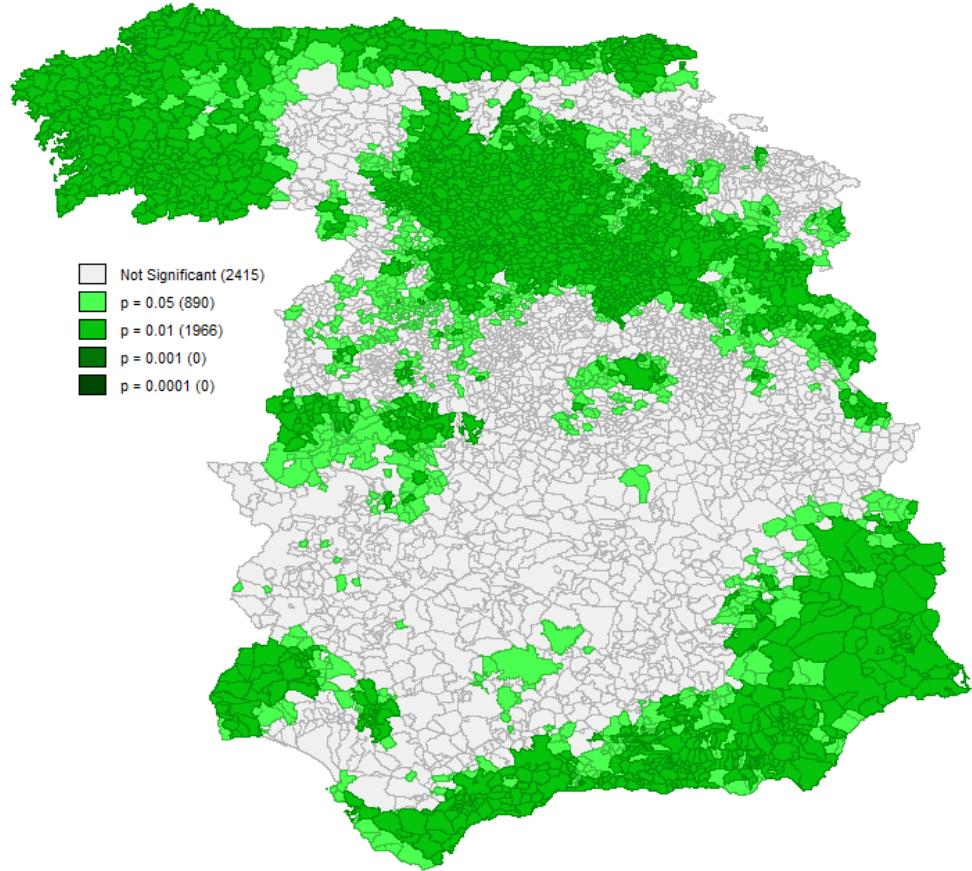

This is not a surprising result and shows that regions with a net surplus of wheat enjoyed lower prices, while those with a net deficit had higher prices. We should also take into account that in the provinces of the northern coast like Galicia maize was the dominant grain while its penetration in the rest of the country was limited due to environmental reasons. It is in maize producing areas where wheat prices reach the highest prices of the sample, probably given its low production. Excluding these provinces from the analysis reinforces the results previously presented and shows that in the areas

¹⁰ Net wheat production was estimated as the production of wheat per head after subtracting the estimated consumption of wheat per head of the population in the region. Therefore, it can be understood as the surplus or deficit in wheat production of each province. We assumed an average consumption of six fanegas per person following Simpson (1989).

where wheat was the dominant grain in both production and consumption, the differences between supply and demand help to explain most of the differences in prices, even when we include in our sample the provinces from the rest of mainland Spain.¹¹

As explained above, we can estimate the levels of spatial autocorrelation for each one of the municipalities included in the study Figures 5 and 6 present the levels of spatial autocorrelation using the Local Moran Statistic calibrated with a distance of 100 kilometres.¹² Figure 5 presents the municipalities in the sample that present spatial autocorrelation at different confidence levels, while Figure 6 adds to the previous if the correlation takes place at high or low prices. Additionally, Figure 6 also includes outliers where Low-High represents municipalities with low prices close to clusters of high prices and High-Low reveals locations with high prices close to clusters of low prices.

Figure 5: Local Moran p-values

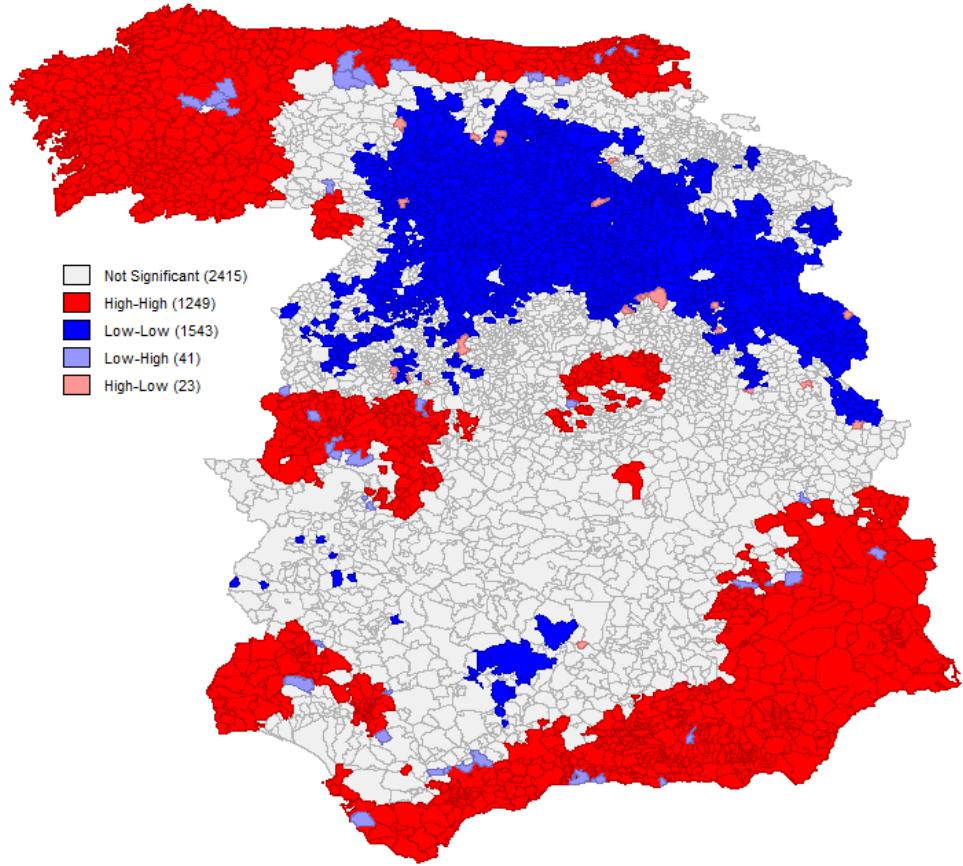

Source: estimates from the Cadastre de la Ensenada

¹¹ The results for the whole of Spain are presented in Table 4 in the Appendix.

¹² Different distance cut-offs were used and the results identified the same regional integration clusters. We also estimated the results using the Queen contiguity criterion that repeats the exercise with the neighbours of each municipality with identical results.

Figure 6: Spatial correlation of wheat prices (Local Moran)

Source: estimates from the Cadastre de la Ensenada

Our results suggest that in the mid-18th century large parts of the Crown of Castile's wheat market were already spatially integrated. Firstly, we observe a high level of spatial autocorrelation in the Mediterranean and Atlantic coasts where prices were high. The other clusters of spatial integration at high prices were located around large urban centres like Madrid, Seville and the north of Extremadura. The largest dominant cluster of spatial integration at low prices could be found in the large grain producing regions of Old Castile mentioned above. A smaller cluster at low prices was identified in the southern plateau and corresponds with the fertile areas in Cordoba where the production of grains occupied an overwhelming amount of land (Ontiveros, 1970).

Our results support most of the findings of the revisionist literature that have studied integration levels using the evolution of price series over time. The large cluster that we identified in Old Castile was also described by Llopis Agelán and Jerez Méndez (2001) who using time series analysis for a smaller sample of locations showed high levels of economic integration between different cities in the region. We also confirm the findings by Gafe (2011) or Chilosi et al. (2013) who using series of prices pointed out the existence of high integration levels in the coast.

The existence of large clusters integrated at different price levels that are geographically very close to each other, reveal the difficulties that existed to integrate areas of the country despite their proximity. Our results show that the grain producing areas of Old Castile were not able to export their surplus to their neighbours in the northern coast. The literature has supported the idea that the wheat from the interior was not able to reach the northern coast where imports from other countries were necessary (Ringrose (1983:178). The same behaviour is also observed in the eastern coast, where imports from Mediterranean producers like Sicily covered a significant share of the consumption (Palop Ramos, 1977). The lack of connection between grain producers in the interior and densely populated areas of the coast help to explain the integration clusters that we observe in our results. While most of the wheat surplus produced in Old Castile remained in the area integrating it at low prices, the high demand in the coast had to be met by international trade that integrated the regions in the coast at high prices.

Analysing our data in a global perspective, more than half of the municipalities included in our study present a high level of spatial integration, a fact revealed by the value of the Global Moran's I that suggests a high average spatial dependence.¹³ On the other hand, the existence of large areas integrated at both high and low prices reveals that this economic integration had a clear regional character and that strong internal barriers existed, as also described by Gafe (2011).

4.2 Determinants of integration

What were the main barriers to economic integration in eighteenth century Spain? The first usual suspect highlighted by the literature is geography. Spain is the country with the second highest average altitude in Europe second only to Switzerland. While the country is dominated by two large plateaus in the interior, it is also crossed by large mountain chains. Low rainfall levels in most Spanish regions also explain the lack of large navigable rivers that could counterbalance the negative effects of geography. Therefore, until the appearance of the railroad in the nineteenth century, the country could only rely on the efficiency of its road network. In the following section we explore the importance of first and second nature variables explaining the different levels of market integration across the territory, and also the role that was played by other variables related to market size.

Table 2 shows the main results of our analysis. At a first glance we confirm our expectations with regards to the role of geography. We find that in both specifications of the OLS, altitude and, in particular, roughness negatively impact integration of pre industrial markets. We seem to find no significant evidence of impact of coast or rivers, perhaps adding to the difficulties that natural barriers such as mountainous masses and absence of navigable rivers create on the accessibility of specific geographical areas, and consistently with the regional clusters described in the previous section.

¹³ See Figure 7 in the Appendix.

| Sargan J-statistic of instrument independence | | | 9.5 | 11.0 |

This table presents the estimates of the OLS and 2SLS regression that measures the impact of First nature, Second nature and market variables on Integration (the inverse of the coefficient of variation of prices for the municipalities within 50 km buffer of each observation), following Equation (1). All the variables are in logarithm except the dummies for Coast and Road. Columns (1) and (2) in Panel 1 present the OLS coefficients and columns (3) and (4) in Panel 2 present the 2SLS results using distance to the roman roads and current rainfall for each 50 km cluster. Cragg–Donaldson Wald F-statistic from the first stage of the 2SLS and Sargan's J-statistic reporting on the validity of instruments are reported at the bottom of the table. Robust standard errors reported in parentheses. Statistical significance denoted by p<0.01, ** p<0.05, * p<0.1

However, our second nature variables OLS coefficients are mildly disappointing since they show small effects of roads on integration. More specifically, column (1) suggests that a municipality being a 10% (some 2.4 km) further from the cartwheel pathway will lead to a 0.4% decrease in terms of integration, while a municipality with direct access to a road is affected by a mere 3.4% higher market integration. There is reason to believe that the cartwheel pathways described in "Itinerario" and

represented in Figure 2 may suffer from reverse causation. As described by the source, many of these paths were informally created by the repeated use of the travellers: one can think that these pathways would never exist if there was no reason to go from one municipality to another. Likewise, local markets could have emerged once they were connected to the road network. We believe that the random sampling of our municipalities avoids the potential problems of reverse causation. However, we understand the potential concerns about endogeneity and intend to address the issue resorting to an instrumental variable strategy.

Based on the evidence from recent research arguing in favour of persistence of the Roman road network on transportation infrastructure, economic activity like Daalgard et al. (2018), and even on market integration, like Flueckiger et al. (2019), we use the availability and distance from our municipalities to the Roman roads network as an instrument for our cartwheel pathways. Despite the argued persistence, and the assumption that cartwheel pathways were easier to arise where there was a previous route, we find that our 18th century road network corresponds to the Roman network only by 16%. Indeed, several of the efforts made by the Romans in the Iberian Peninsula did not persist through the 18th century.¹⁴ Although, both networks naturally connect many main cities, distance to both networks varies radically for many of our municipalities. Thus, we argue that the ancient Roman roads do not necessarily affect the integration of the markets in the Crown of Castile. For a graphical comparison of both networks, see Figure A1 in the Appendix. Following, Miguel et al. (2004) we also use the level of rainfall across our different municipalities provided by the Spanish National Meteorological Agency (Ministerio de Medio Ambiente (2005) as an additional instrument which could determine the quality and amount of our cartwheel pathways but not necessarily the level of market integration.

Columns (3) and (4) show the results of an analogous analysis using 2SLS with distance to the Roman roads and rainfall municipal levels as instruments for availability (3) and distance to 18th century roads (4) from our municipalities. First of all, the table shows that the first stage is strong and the instrument is valid according to the F-statistics and J-statistics reported in the table. Compared to OLS, we observe that the effect of the roads is now certainly much more important, implying that municipalities having direct access to the road network are 166% ($10^{0.426}-1$) more integrated than remote ones. We are also revealed that, once the effect of the roads is properly measured, the coefficients for the first nature variables, altitude and roughness become insignificant. Therefore, when roads take into account possible endogeneity problems such as reverse causality, we observe that municipalities with access to the road network were able to overcome the obstacles imposed by geography, diminishing part of the effect of demand side variables as well. This result supports the ideas presented by Santiago-Caballero (2009) in eighteenth century Spain, suggesting that the benefits of the road network reducing price volatility was higher in those areas where the time to walk one league, used as a proxy of the difficulty of the terrain, was longer. As Gafe (2013) also pointed out, although we do believe that a disadvantageous geography played a significant role in

¹⁴ According to several sources the main motivation behind the Roman roads were military (Daalgard et al., 2018). These are entirely different to the spontaneous rise of our cartwheel pathways, mainly motivated by local economic reasons.

explaining the lack of a larger market in eighteenth century Spain, we also observe evidence supporting that the road network was able to reduce the negative effects of geographical constraints.

However, given the radial shape of the road network we feared that the coefficients might have been affected by spatial autocorrelation. Consistent to this and the previous cluster analysis, the 2SLS results motivate a further test that controls for spatial dependence. Recall that local autocorrelation indicators (LISA) were reported for prices in all municipalities within the Castilian territory, and we now have a sample of 351 municipalities for an integration coefficient that summarizes their neighbours within the 50 km band. Not surprisingly, Global Moran's statistics (I) for the sample variables indicate that all the variables are significantly spatially correlated (see Table 5/Figure 7 in the Appendix). Thus, we decided to test for spatial dependence in our previous results.

Table 3: Diagnostic tests for spatial dependence

| Test | Statistic | df | p-value |
|----------------------------|-----------|----|---------|
| Spatial error: | | | |
| Moran's I | 0.002 | 1 | 0.998 |
| Lagrange multiplier | 0.001 | 1 | 0.978 |
| Robust Lagrange multiplier | 0.011 | 1 | 0.915 |
| Spatial lag: | | | |
| Lagrange multiplier | 0.286 | 1 | 0.593 |
| Robust Lagrange multiplier | 0.297 | 1 | 0.586 |

Notes: Diagnostic test for spatial dependence in OLS regression residuals using an inverse weights distance matrix with a cut-off of 100 km. Alternative matrixes have been tested leading to different results but similar conclusions.
Statistical significance denoted by p<0.01, ** p<0.05, * p<0.1

Table 3 shows that despite the variable statistical autocorrelation, we can ensure that the previous OLS/2SLS specifications take good care of the spatial correlations on their own. As shown in the table, there is no evidence of spatial autocorrelation in the residuals, since the Moran's I is very small and insignificant. More than this, the Lagrange Multiplier tests for both lag and error dependence are insignificant, implying that the OLS/2SLS is the most plausible strategy. Additionally, both spatial coefficients (*rho* in the Spatial Lag Model and *lambda* in the Spatial Error Model) and their standard errors presented in Table 6 in the appendix imply that adjusting for the spatial weights matrix brings no improvement to our previous strategy.

5. Conclusions

Defining the moment when the Spanish market became fully integrated is crucial to explain its long-term economic performance. The traditional literature argued that it was not until the nineteenth century, with the introduction of the railroad, that markets became integrated in Spain. The reasons for the delay were the difficulties imposed by geography and the lack of efficient transportation

alternatives to roads like canals and navigable rivers. However, a revisionist literature pointed out that by the eighteenth century, Spain had already reached significant levels of market integration. Our study builds up within this historiographical debate using alternative data and methods to the typically used in the literature. We focus on the analysis of a large cross-section of local level wheat price observations and study their spatial autocorrelation instead of focusing on convergence and covariance of price time series.

Our approach is therefore different in the kind of evidence that it can provide and in the level of detail that we can present in geographical terms. Although we can only analyse integration levels in a snapshot, the high geographical coverage and the size of our sample allows us to identify clusters of spatial integration of prices in a level of detail that could not be achieved with a smaller number of locations. We extracted information from more than 5,200 books from the Cadastre de la Ensenada, a survey carried out at municipal level in mid-eighteenth century Spain. Our results show that taken globally, spatial integration levels were very high, but also that a detailed analysis of the data reveals the existence of regional integration clusters that are not connected with each other. Therefore, we reject the existence of a national market and support the results of previous research suggesting the existence of well integrated regional markets. The nature and scope of our data also allowed us to study if the clusters were integrated at high or low prices. In this sense, we identified a large regional cluster integrated at low prices that corresponds to the grain producing regions of Old Castile. The main clusters integrated at high prices were located around large urban areas like Madrid and in coastland regions. The lack of integration between these clusters explain why they are integrated at different price levels, as the oversupply of grain from Old Castile could not reach peripheral markets reducing local prices, while urban and coastland densely populated areas could not access to the production of the interior and had to rely on international imports, explaining both the high integration along the coast and the high prices. We then explore the drivers of the regional integration and global disintegration and show that, at least partially, the transportation network available in mid-18th century Spain helped overcome the negative role of its geography allowing regional clusters to integrate, however these regional clusters were locked in probably until the arrival of the steam engine when Spain could become a nationally integrated market.

These results provide evidence in favour of the revisionist literature and are crucial to the understanding of the patterns and drivers of market integration. The case of mid-18th century Spain illustrates that unfavourable nature can be overcome by infrastructures, providing useful insights for policymakers who can conclude that even when facing negative geographical endowments, investment in transportation infrastructures can lead to market integration.

Methodological appendix

The local estimator of Moran's (I) statistic for municipality i is estimated using the following equation:

$$I_i = z_i \sum_j w_{ij} z_j \quad (2)$$

Where Zi is the original value of the variable xi in the standardised form.

$$z_i = \frac{x_i - \bar{x}}{SD_x} \quad (3)$$

wij are the weights that correspond in the spatial matrix that take value 1 when the municipality is within a defined distance from the municipality analysed and 0 otherwise.

The second statistic that we used in our study is the local G Getis-Ord, that is defined by the following equation:¹⁵

$$G_i(d) = \frac{\sum_j w_{ij}(d)x_j}{\sum_j x_j} \quad (4)$$

Where wij(d) is a symmetrical spatial weights matrix (1/0) with value 1 for those municipalities located within a distance "d" from municipality i and 0 otherwise, including the value for municipality I where:

$$Wi = \sum_{j \neq i} w_{ij}(d) \quad (5)$$

The numerator of equation 3 is the sum of all the xj within distance "d" from municipality I excluding its own value. The denominator is the sum of all the xj excluding xi.

¹⁵ For a more detailed explanation on these technical issues, check Getis and Ord (1992)

We estimated these indicators using GEODA, a spatial analysis software package developed by the spatial economist Luc Anselin, which offers the possibility to graphically represent the estimated results. The shapefiles available for the application are only for current territories, and the software cannot handle missing observations, so we had to create our own shapefile for the territory belonging to the Crown of Castile.

| Number of observations | 352 | | | | |

Note: this table shows the spatial diagnostics of the variables in our baseline specification. The Moran's Indexes have been obtained using an inverse distance spatial weights matrix in with a threshold of 100 km and a decay parameter of 2. All the variables show a statistically significant deviation from the expected value E(I) under the null hypothesis of spatial randomization. Other specifications lead to different indicators but similar conclusions.

Table 6: Spatial Regression Models

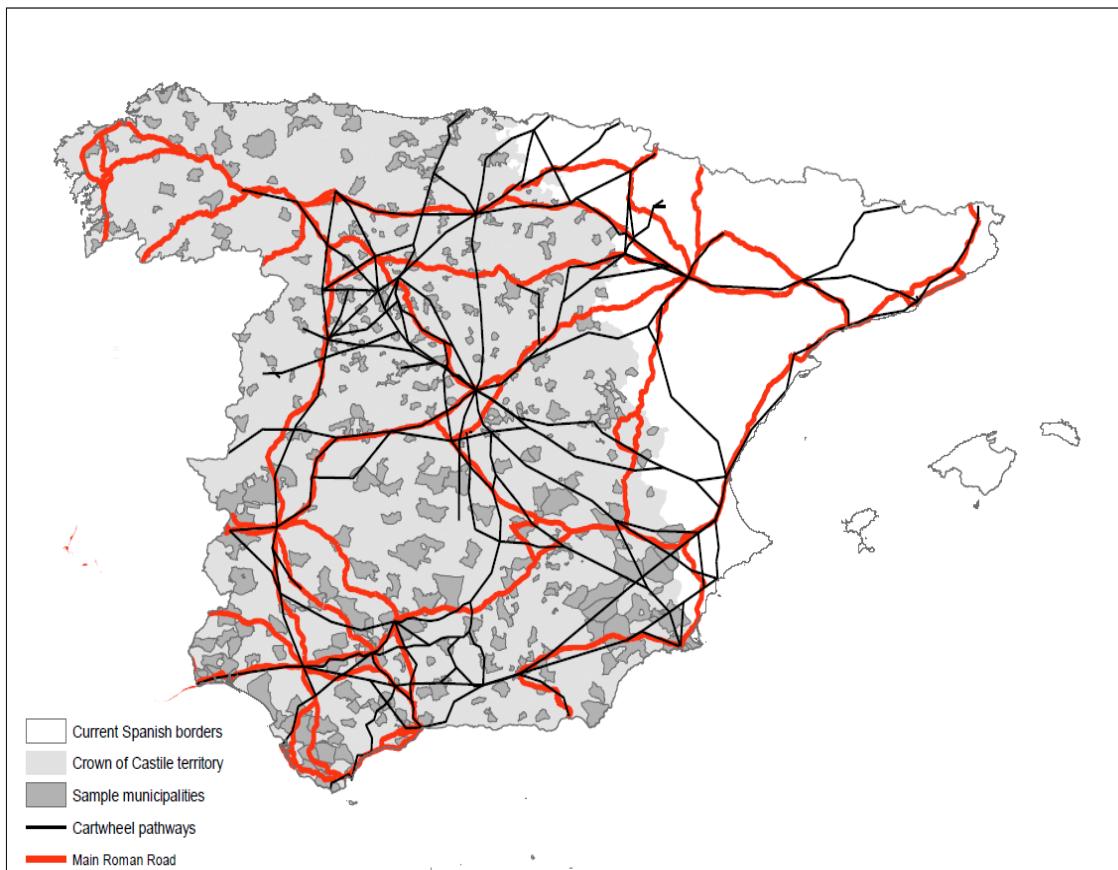

| | (1) <i>Spatial Lags Model</i> | (2) <i>Spatial Error Model</i> |
|--|----------------------------------|-----------------------------------|
| <i>First nature</i> | | |
| Altitude | -0.17*** (0.061) | -0.17*** (0.061) |
